## ABSTRACT

Water is key in the evolution of protoplanetary disks and the formation of comets and icy/water planets. While high excitation water lines originating in the hot inner disk have been detected in several T Tauri stars (TTSs), water vapor from the outer disk, where most of water ice reservoir is stored, was only reported in the closeby TTS TW Hya. We present spectrally resolved *Herschel*/HIFI observations of the young TTS DG Tau in the ortho- and para- water ground-state transitions at 557, 1113 GHz. The lines show a narrow double-peaked profile, consistent with an origin in the outer disk, and are  $\sim 19 - 26$  times brighter than in TW Hya. In contrast, CO and [C II] lines are dominated by emission from the envelope/outflow, which makes H<sub>2</sub>O lines a unique tracer of the disk of DG Tau. Disk modeling with the thermo-chemical code ProDiMo indicates that the strong UV field, due to the young age and strong accretion of DG Tau, irradiates a disk upper layer at 10–90 AU from the star, heating it up to temperatures of 600 K and producing the observed bright water lines. The models suggest a disk mass of 0.015–0.1 M<sub>⊙</sub>, consistent with the estimated minimum mass of the solar nebula before planet formation, and a water reservoir of  $\sim 10^2 - 10^3$  Earth oceans in vapour, and  $\sim 100$  times larger in the form of ice. Hence, this detection supports the scenario of ocean delivery on terrestrial planets by impact of icy bodies forming in the outer disk.

*Subject headings:* astrochemistry - ISM: molecules - protoplanetary disks - stars: individual (DG Tau)

## 1. INTRODUCTION

Protoplanetary disks are the birthplaces of planets, thus the study of their physical and chemical structure is fundamental to comprehend the formation of our own solar system as well as of extra-solar planetary systems. One of the most intriguing issues on planet formation concerns the origin of oceans on Earth. It was argued that Earth formed "dry" and that ocean water was delivered by impacts of icy bodies/protocomets originating from the cold outer disk, where most of the mass (and water reservoir) is located (Matsui & Abe 1986). To address this issue, many efforts have been devoted to observe water in protoplanetary disks and to characterize its abundance and spatial distribution.

In the hot dense inner disk region inside the so-

called 'snow line' where  $T_{\text{dust}} \sim 150$  K, i.e. for radii smaller than  $\sim 1 - 3$  AU in disks around T Tauri Stars (TTSs) (Lecar et al. 2006), ice cannot exist on dust grains and gas-phase chemistry converts all oxygen into water on timescales short compared to the disk evolution timescale. Beyond the snow-line, instead, water molecules will be frozen onto dust grains. However, (inter)stellar UV and X-ray radiation can penetrate in the disk upper layers and photo-desorb a fraction of water ice back into the gas phase (Ceccarelli et al. 2005; Dominik et al. 2005). The released water vapour may be eventually dissociated and re-formed in the gas-phase.

H<sub>2</sub>O lines with upper level energies  $E_{\text{up}} > 1000$  K, tracing hot water vapor in the inner disk regions, have now been observed in a number of protoplanetary disks thanks to ground-based and Spitzer near- and mid-infrared observations (e.g. Carr & Najita 2008; Salyk et al. 2008; Pontoppidan et al. 2010a,b), and, recently, far-infrared observations of the 63.32  $\mu\text{m}$  line with *Herschel* (Riviere-Marichalar et al. 2012). In contrast, cold water vapor at  $T < 200$  K from the outer disk surface has turned out surprisingly difficult to detect in TTSs. *Herschel*/PACS detected the low excitation H<sub>2</sub>O 179.5  $\mu\text{m}$  line ( $E_{\text{up}} = 114$  K) only in jet-driving stars but due to the lack of spatial and velocity information, it is unclear if it originates in the disk or in the envelope/outflow (Podio et al. 2012). Up to now, firm evidence for a cold disk water reservoir has been found only in the nearby ( $d \sim 50$  pc) TTS TW Hya, through the detection of the fundamental ortho and para lines at 557 and 1113 GHz with *Herschel*/HIFI (Hogerheijde et al. 2011). While o-H<sub>2</sub>O 557 GHz line profiles in Class 0 and I sources show velocities of  $\sim 11 - 138$  km s<sup>-1</sup>, and  $\sim 5 - 54$  km s<sup>-1</sup>, suggesting they are dominated by emission from the envelope/outflow (Kristensen et al. 2012),

the H<sub>2</sub>O emission from TW Hya shows a narrow single-peaked profile ( $FWHM \sim 0.96 - 1.2 \text{ km s}^{-1}$ ) consistent with an origin in the face-on disk. A hidden reservoir of icy bodies of  $1.5 M_{\oplus}$ , equivalent to several thousands of Earth oceans<sup>11</sup> is inferred. Additional studies are necessary to investigate this hypothesis, but only upper limits were obtained toward a couple of other TTSs targeted with HIFI, e.g. DM Tau (Bergin et al. 2010).

DG Tau is a young TTS at 140 pc associated with particularly strong accretion/outflow activity (e.g. Hartigan et al. 1995; Dougados et al. 2000), and where we previously detected unresolved emission in the H<sub>2</sub>O 78.7, 179.5  $\mu\text{m}$  lines with *Herschel*/PACS (Podio et al. 2012). In this Letter, we present clear detections of the H<sub>2</sub>O 557, 1113 GHz lines towards this source.

## 2. OBSERVATIONS AND DATA REDUCTION

We observed DG Tau ( $\alpha_{J2000} = 04^{\text{h}} 27^{\text{m}} 04^{\text{s}}.7$ ,  $\delta_{J2000} = +26^{\circ} 06' 16''.3$ ) with the Heterodyne Instrument for the Far Infrared (HIFI, de Graauw et al. 2010) on board the *Herschel* Space Observatory<sup>12</sup> (Pilbratt et al. 2010). The observations target the two fundamental water lines, o-H<sub>2</sub>O  $1_{10}-1_{01}$  and p-H<sub>2</sub>O  $1_{11}-0_{00}$ , the <sup>12</sup>CO (hereafter CO) and <sup>13</sup>CO 10–9, and the [C II]  $2P_{3/2}-2P_{1/2}$  lines (OB-SID: 1342239630, 1342250208, 1342249594, 1342249646). They were acquired in the HIFI bands 1, 4, 5, and 7, with a single on-source pointing and in dual beam switch mode with fast chopping 3' either side of the target. The Wide Band Spectrometer (WBS) and the High Resolution Spectrometer (HRS) were used in parallel, with a spectral resolution of 1.10 and 0.25 MHz, respectively. The Half Power Beam Width (HPBW) ranges from  $\sim 11''$  to  $\sim 38''$ , depending on frequency.

HIFI data were reduced using HIPE 8<sup>13</sup>. Fits files from level 2 were then created and transformed into GILDAS<sup>14</sup> format for data analysis. The spectra were baseline subtracted and then resampled at  $0.6 \text{ km s}^{-1}$  to increase the sensitivity. Note that the V-spectrum of the o-H<sub>2</sub>O and p-H<sub>2</sub>O lines are affected by ripples, degrading the quality of the baseline and resulting in an rms larger than the one measured in the H-spectrum. Therefore, in the following, we will analyse the o-H<sub>2</sub>O and p-H<sub>2</sub>O emission based solely on the H-spectrum.

The HIFI dataset is complemented by observations of the CO 3–2 line performed on January 2010 at the JCMT 15m telescope (Maunakea, Hawaii, USA) using the HARP-B heterodyne array and ASCIS correlator, providing a spectral resolution of  $0.25 \text{ km s}^{-1}$ . The spectrum was resampled at  $0.6 \text{ km s}^{-1}$  to be compared with the HIFI data.

Antenna temperatures,  $T_a$ , are converted to mean beam temperature,  $T_{\text{mb}}$  (for HIFI mean beam efficiency are by Roelfsema et al. 2012). Integrated line intensities,  $\int T_{\text{mb}} dV$ , and line fluxes,  $F_{\text{obs}} = \frac{2K_b \nu^3}{c^3} \times \int T_{\text{mb}} dV \times$

<sup>11</sup>  $1 M_{\oplus} = 5.97 \cdot 10^{27} \text{ g}$ , 1 Earth ocean  $\simeq 1.5 \cdot 10^{24} \text{ g}$

<sup>12</sup> *Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

<sup>13</sup> HIPE is a joint development by the *Herschel* Science Ground Segment Consortium, consisting of ESA, the NASA *Herschel* Science Center, and the HIFI, PACS and SPIRE consortia.

<sup>a</sup>All lines are observed with *Herschel*/HIFI except CO 3–2 which is observed with JCMT/HARP-B

<sup>b</sup>Frequencies are from the Jet Propulsion Laboratory molecular database (Pickett et al. 1998)

$\pi \left( \frac{\text{HPBW}}{2\sqrt{\ln 2}} \right)^2$ , are summarized in tables 1 and 3.

## 3. RESULTS FROM OBSERVATIONS

The observed line profiles are shown in figure 1. The JCMT CO 3–2 line profile in panel (a) suggests that the systemic velocity is  $V_{\text{sys}} \sim +6.2 \text{ km s}^{-1}$ , consistent with previous studies (Schuster et al. 1993; Kitamura et al. 1996; Testi et al. 2002).

We detect both the ortho-H<sub>2</sub>O  $1_{10}-1_{01}$  557 GHz and the para-H<sub>2</sub>O  $1_{11}-0_{00}$  1113 GHz lines ( $E_{\text{up}} \sim 61, 53 \text{ K}$ ) with a signal-to-noise of 10 and 12, respectively. They are centered at the systemic velocity and show a narrow double-peaked profile ( $FWHM \sim 5 - 6 \text{ km s}^{-1}$ ).

CO 10–9, <sup>13</sup>CO 10–9, and [C II] 158  $\mu\text{m}$  lines have a different profile than H<sub>2</sub>O, with a single peak near systemic velocity (at  $V_{\text{LSR}} = +6.5 \text{ km s}^{-1}$  in CO and  $+5.5 \text{ km s}^{-1}$  in [C II]), and a pronounced blue wing extending down to 0 and  $-5 \text{ km s}^{-1}$  respectively (i.e. 6 and  $11 \text{ km s}^{-1}$  away from systemic). The bulk of CO and [C II] emission close to systemic velocity likely originates in the envelope, as suggested by the <sup>13</sup>CO 2–1 channel maps by Testi et al. (2002) that indicate emission extended over  $\simeq 10''$  at velocities  $|V - V_{\text{sys}}| < 1.5 \text{ km s}^{-1}$ . The observed blue wing, instead, may originate in a slow outflow, perhaps linked to envelope dispersal motions as proposed by Kitamura et al. (1996). For the [C II] 158  $\mu\text{m}$  line an origin in an extended structure is further confirmed by the fact that the flux in the HIFI beam of  $\sim 11''$  is  $\sim 4$  times lower than the total co-added flux in the *Herschel*/PACS observations ( $47'' \times 47''$ , Podio et al. 2012).

On the other hand, several arguments suggest that the H<sub>2</sub>O emission is compact and is likely dominated by emission from the outer region of the protoplanetary disk of DG Tau, and not from the envelope/outflow:

- The H<sub>2</sub>O line profiles are different from those of CO and [C II] observed with single-dish telescopes. They are much more symmetric about the systemic velocity and do not show the extended blue wing seen in these other tracers.
- The peaks of the H<sub>2</sub>O line profiles coincide with the two narrow velocity ranges ( $|V - V_{\text{sys}}| = 1.5 - 2.5 \text{ km s}^{-1}$ ) where <sup>13</sup>CO 2–1 interferometric maps show compact emission with a velocity gradient perpendicular to the jet axis, consistent with disk rotation (Testi et al. 2002). The <sup>13</sup>CO 2–1 line profile obtained by integrating the interferometric maps by Testi et al. (2002) over a  $2''$  beam, i.e. by

FIG. 1.— HIFI spectra of (a)  $\text{o-H}_2\text{O } 1_{10}-1_{01}$  (grey histogram); (b)  $\text{p-H}_2\text{O } 1_{11}-0_{00}$  (grey histogram); (c)  $\text{CO } 10-9$ ,  $^{13}\text{CO } 10-9$ , and  $[\text{C II}] \text{ } ^2\text{P}_{3/2}-^2\text{P}_{1/2}$  (green, red, and blue histograms, respectively). In panel (a) JCMT  $\text{CO } 3-2$  (red histogram), and  $^{13}\text{CO } 2-1$  profile obtained integrating interferometric maps by Testi et al. (2002) on a  $2''$  beam (blue histogram) are also shown. The vertical dotted line indicates the systemic velocity ( $V_{\text{LSR}} = +6.2 \text{ km s}^{-1}$ ). The  $\text{H}_2\text{O}$  line profiles predicted by the “low dust opacity” ProDiMo disk model are overplotted (magenta lines). The  $\text{o-H}_2\text{O}$  line flux is underpredicted by the model by a factor  $\sim 2.2$ , hence the line profile is multiplied by this factor to help the comparison with observations.

cutting out any extended component, is similar to the  $\text{H}_2\text{O}$  line profiles, with peaks at the same velocities. In contrast, the  $\text{CO } 3-2$  profile, obtained with the JCMT collecting all the emission in the  $14''$  beam, does not peak at the same velocity as the  $\text{H}_2\text{O}$  and  $^{13}\text{CO}$  compact component. This is particularly clear in the blue part of the profile.

- Assuming keplerian rotation, and an inclination of  $i \simeq 38^\circ$  from the line of sight (Eisloffel & Mundt

1998) the peak separation of the  $\text{H}_2\text{O}$  lines ( $\Delta V_{\text{sep}} \sim 3-3.5 \text{ km s}^{-1}$ ) indicates an outer disk radius  $R_{\text{out}}(\text{H}_2\text{O}) \sim 77-105 (M_*/0.7 M_\odot) \text{ AU}$ . For a stellar mass of  $\sim 0.7 M_\odot$ , as assumed in Testi et al. (2002), the inferred  $R_{\text{out}}(\text{H}_2\text{O})$  is in agreement with the disk outer radius,  $\sim 72-89 \text{ AU}$ , estimated from sub-arcsecond dust continuum maps at 1.3, 2.8 mm with CARMA (Isella et al. 2010). The maximum velocities covered by the line profiles, instead, set an upper limit to the inner radius of the line emitting region  $R_{\text{in}}(\text{H}_2\text{O}) \leq 19 \text{ AU}$ , since more extended line wings could be hidden in the noise.

- The  $\text{H}_2\text{O}$  line profiles are reproduced by an optically thick, vertically isothermal keplerian disk with  $T_{\text{ex}} \propto r^{-0.5}$  viewed at  $38^\circ$  with an excitation temperature at  $R_{\text{out}}$  of 70 and 32 K for the ortho and para lines respectively (Beckwith & Sargent 1993; Cabrit et al. 2006).

Given the evidence listed above, the fundamental water lines, even when observed with a  $38''-19''$  beam, appear to be dominated by compact emission. Although we cannot exclude contamination from the outflow, which could explain the larger FWHM and the asymmetry of the  $\text{o-H}_2\text{O } 557 \text{ GHz}$ , the detected double-peaked  $\text{H}_2\text{O}$  lines prove to be a good tracer of the outer protoplanetary disk of DG Tau, with less confusion from envelope/outflow than in  $^{13}\text{CO}$ .

DG Tau shows emission also in high-excitation  $\text{H}_2\text{O}$  lines observed with PACS (Podio et al. 2012). With  $E_{\text{up}} \sim 200-1070 \text{ K}$  these are thought to originate in an intermediate disk region between a few and a few tens of AU from the star (e.g. Riviere-Marichalar et al. 2012). The exception is the low-excitation  $\text{H}_2\text{O } 179.5 \mu\text{m}$  line ( $E_{\text{up}} \sim 114 \text{ K}$ ) which according to previous disk modeling is predicted to form in the outer disk like the 557, 1113 GHz lines (Kamp et al. submitted). The observed  $\text{H}_2\text{O } 179.5 \mu\text{m} / 557 \text{ GHz}$  line ratio is  $R_{1\text{obs}} = 25 \pm 6$ , consistent with LTE optically thick emission in the Rayleigh-Jeans limit, i.e. for temperatures larger than a few hundreds K ( $R_{\text{LTE-thick}} \sim 27$ ). On the other hand, the line ratio between the para- and the ortho-fundamental lines ( $R_{2\text{obs}} = 2.5 \pm 0.3$ ) is around three times lower than  $R_{\text{LTE-thick}} \sim 8$ . This can be explained if the lines are excited in a region where the gas density is lower than the lines critical density ( $\sim 2 \cdot 10^7$  and  $\sim 2 \cdot 10^8$  at 50 K for the 557 and 1113 GHz lines) and/or where the temperature is below their upper level energies. Also, the observed line ratio could be affected by emission from the envelope/outflow.

#### 4. MODELING $\text{H}_2\text{O}$ IN THE DISK OF DG TAU

Detailed disk modeling is required to test the disk hypothesis and to derive an estimate of the water mass. The latter cannot be inferred from observations since the lines are likely optically thick. We include in our analysis the fluxes and upper limits obtained for the water lines falling between 63.3 and 180.5  $\mu\text{m}$  observed with PACS as part of the *Herschel* Key Project GASPS (PI: B. Dent) (Podio et al. 2012). The two detected  $\text{o-H}_2\text{O}$  lines at 78.7 and 179.5  $\mu\text{m}$  are spectrally and spatially unresolved, thus their origin is unclear. In Podio et al.

FIG. 2.— Disk region from which 50% of the o-H<sub>2</sub>O 179.5  $\mu$ m (in green), o-H<sub>2</sub>O 538.3  $\mu$ m (or 557 GHz, in red), and p-H<sub>2</sub>O 269  $\mu$ m (or 1113 GHz, in orange) line emission arises according to the “low dust opacity” disk model. The grey colour indicates the water density,  $n_{\text{H}_2\text{O}}$  ( $\text{cm}^{-3}$ ), the dotted black and blue curves the gas temperature and density, and the white solid curve the snow-line (i.e.  $T_{\text{dust}} = 150$  K).

(2012) a shock-origin was favoured based on the large line fluxes, which are difficult to reproduce with disk models for typical TTSs parameters. However, since the profiles of the ground-state water lines are consistent with a disk origin, we test the predictions of a dedicated model for DG Tau by comparing them with observed H<sub>2</sub>O line fluxes and profiles.

We use a parametrized disk model calculated with the thermo-chemical disk modeling code ProDiMo (Woitke et al. 2009; Kamp et al. 2010). We adopt the stellar spectral type K7 ( $T_{\text{eff}} \simeq 4000$  K) and veiling-corrected stellar radius of  $1.8 R_{\odot}$  (Fischer et al. 2011). The resulting stellar luminosity  $\simeq 1 L_{\odot}$  yields a stellar mass  $M_{\star} \simeq 0.7 M_{\odot}$  and an age of  $2.5 \times 10^6$  yr using the evolutionary tracks of Siess et al. (2000). To reproduce the IUE UV/optical spectrum (Gullbring et al. 2000), we set the UV excess fraction  $f_{\text{UV}} = L(910 - 2500 \text{ \AA})/L_{\star} = 0.2$  and adopt a power law slope  $L_{\lambda} \approx \lambda^{-0.3}$ . We also account for the effect of X-ray radiation from the stellar corona ( $L_{\text{X}} = 10^{30} \text{ ergs}^{-1}$ , Güdel et al. 2007) following Aresu et al. (2011); Meijerink et al. (2012). The disk inner and outer radius are set to  $R_{\text{in}} = 0.16$  AU (Akeson et al. 2005), and  $R_{\text{out}} = 100$  AU, in agreement with  $R_{\text{out}}(\text{H}_2\text{O})$  inferred from the observed H<sub>2</sub>O profiles. We assume the dust size distribution and disk dust mass from the “low dust opacity model” — a 50/50 mixture of astronomical silicates (Draine & Lee 1984) and amorphous carbon (Zubko et al. 1996) — used by Isella et al. (2010) to reproduce the observed 1.3, 2.8 mm emission ( $n(a) \approx a^{-q}$  with  $q = 3.5$ , where  $a$  is the dust grain radius, the minimum/maximum grain size are  $a_{\text{min}} = 0.005 \mu\text{m}$  and  $a_{\text{max}} = 5 \text{ cm}$ ). Using the standard dust-to-gas ratio of 0.01 the gas mass is set to  $0.1 M_{\odot}$ . The disk is thought to be perpendicular

to the jet, thus  $i = 38^{\circ}$  (Eisloffel & Mundt 1998). We assume a parametrized disk shape with surface density  $\Sigma \approx r^{-1}$ , and scale height  $H = 0.008 \text{ AU } (r/0.16 \text{ AU})^{1.2}$ . No dust settling is invoked, i.e. dust and gas are well mixed throughout this young disk. The PAH fraction is 0.01 with respect to the ISM abundance of  $10^{-6.52}$  PAH particles/H-nucleus. All parameters adopted for the model are summarized in table 2.

The line profiles and fluxes are obtained by first solving the statistical equilibrium with 2D escape probability to obtain the level populations, and then using 2D radiative transfer (collision rates as listed in table 3 of Kamp et al., submitted). The region from which 50% of the H<sub>2</sub>O line emission arises, instead, is obtained using vertical escape probability and without accounting for disk inclination. Figure 2 indicates that the H<sub>2</sub>O 179.5  $\mu$ m line observed with PACS originates in the same region as the fundamental water lines at 557, 1113 GHz observed with HIFI, i.e. in an upper disk layer ( $z/r \sim 0.35 - 0.6$ ) located at  $\sim 10 - 90$  AU distance from the star. In this region the gas temperature is  $\sim 50 - 600$  K and water is formed mainly through gas-phase reactions and partially dissociated by UV photons and collisions with C<sup>+</sup> and H<sup>+</sup>. Including self-shielding for all photodissociating species produces at most 20% lower fluxes. The gas density is  $10^8 - 10^{10} \text{ cm}^{-3}$  thus, as suggested by the observed H<sub>2</sub>O 179.5  $\mu$ m/557 GHz line ratio, these lines are close to LTE and optically thick ( $\tau \sim 10^3 - 10^4$ ). The ortho-to-para ratio (OPR) is calculated from the gas temperature at thermal equilibrium and is 1.5–3 in the line emitting region. However, since the H<sub>2</sub>O lines are optically thick, the model results are not dependent on the OPR.

As shown in figure 1 the model reproduces the p-H<sub>2</sub>O line flux and profile, and the ratio o-H<sub>2</sub>O 179.5  $\mu$ m / 557 GHz is  $R_{1\text{mod}} \simeq 25$ , in agreement with the observed value. On the other hand, the observed ortho lines at 179.5  $\mu$ m and 557 GHz are underpredicted by a factor  $\sim 2$ . As a consequence the observed p-H<sub>2</sub>O 1113 / o-H<sub>2</sub>O 557 line ratio is overpredicted by a factor 2.4 ( $R_{2\text{mod}} = 6.1$ ). Kamp et al. (submitted) discuss in detail the uncertainties when modeling water emission in disks. They show that the assumed surface chemistry, adsorption energy and photo-desorption yields, and metal abundances can affect water line fluxes by a factor of a few. In particular, the low-excitation water lines are very sensitive to the adopted radiative transfer method and to the uncertainties in the collision rates. Moreover the disk model is not accounting for the X-ray emission by the jet (Güdel et al. 2008) which illuminates the disk surface from above. This may boost water formation through H<sub>3</sub>O<sup>+</sup> recombination ( $\text{H}_3\text{O}^+ + e^- \rightarrow \text{H}_2\text{O} + \text{H}$ , Meijerink et al. 2012). In general, the model can reproduce all the H<sub>2</sub>O lines observed with PACS and HIFI within a factor 2 (see table 3). The emission in the CO and [C II] lines is predicted to be a factor 3–9 lower than observed, which is in agreement with the observed profiles indicating that the bulk of the emission originate from the envelope/outflow.

The disk model indicates that the disk contains  $\sim 0.4 M_{\oplus}$  of water vapour, and two orders of magnitude larger mass in ice:  $M(\text{H}_2\text{O}\#) \sim 100 M_{\oplus}$ . To understand the reliability of the estimated water mass in the disk, we calculate a second model assuming the dust size distribution

and disk dust mass from the “high dust opacity model” by Isella et al. (2010). This implies around an order of magnitude lower dust mass in the disk and consequently around an order of magnitude lower gas mass, and water vapor and ice mass ( $M_{\text{gas}} = 0.015 M_{\odot}$ ,  $M(\text{H}_2\text{O}) \sim 0.06 M_{\oplus}$ ,  $M(\text{H}_2\text{O}\#) \sim 7 M_{\oplus}$ ). We find that this model can reproduce equally well the observed  $\text{H}_2\text{O}$  line fluxes, because the “high dust opacity model” implies lower opacity at UV wavelengths and thus a deeper UV penetration in the outer disk regions. Hence, the dust size distribution is crucial to constrain the disk mass and water reservoir, leading to an uncertainty of one order of magnitude.

The total water reservoir,  $M(\text{H}_2\text{O})_{\text{gas+ice}} \sim 7 - 100 M_{\oplus}$ , is a factor of a few up to two orders of magnitude larger than for TW Hya (Hogerheijde et al. 2011).

## 5. CONCLUSIONS

The present detection of the o- $\text{H}_2\text{O}$  and p- $\text{H}_2\text{O}$  lines at 557, 1113 GHz in the TTS DG Tau is crucial for several reasons: (i) so far, emission in the fundamental water lines has been observed only in one TTS, TW Hya; (ii) we detect for the first time a double-peaked profile in the  $\text{H}_2\text{O}$  lines, which is a strong kinematic evidence for an origin in the outer disk (from  $\sim 10 - 90$  AU); (iii) water turns out to be a unique tracer of the protoplanetary disk of DG Tau, because is less contaminated by envelope/outflow emission than CO lines; (iv) once corrected for distance the  $\text{H}_2\text{O}$  lines are  $\sim 19 - 26$  times brighter than in TW Hya. According to our models, the reason is the 10 times higher UV flux of DG Tau, which heats the outer disk surface layer up to temperatures of  $\sim 600$  K (only  $\sim 30$  K in the case of TW Hya). In addition, the disk around DG Tau is more massive and compact leading to higher volume densities in the surface layers, which makes the warm neutral chemistry even more efficient; (v) the adopted models suggest a disk mass of  $0.015 - 0.1 M_{\odot}$ , depending on the assumed dust size distribution, and a water reservoir (gas+ice) of  $7 - 100 M_{\oplus}$ , i.e. at least a factor of a few larger than estimated for TW Hya (Hogerheijde et al. 2011).

While the inferred disk mass is consistent with the minimum mass of the solar nebula to form our solar system, the detection of water vapor in the outer region of the disk, where comets are believed to form, and the estimated water mass of a few  $\sim 10^4 - 10^5$  Earth oceans, supports the scenario of impact delivery of water on terrestrial planets by means of icy bodies.
